

1) **The “Gauss Clock” timing framework seems adequate.**

AC dipole timing scans give polarization dependence close to expectations.

Magnetic “flat tops” at correct $G\gamma$. No tuning of the intermediate porches necessary. If Woody’s sharp polarization loss spikes are at (.3 and .7) on 46.5 porch then our position is nearly perfect. *Fig 1*

However calibration measurements no so robust during the run. (gold work)

2) **Intensity dependence of measured polarization in AGS (?) and the poor polarization over the last shift of the run – effects not yet cleanly understood.**

Plot of some (Pol vs Int) from the last two weeks of the run. *Fig 2*

3) **AC Dipole behavior and associated beam behavior.**

Deterioration (over the run) of the beam coherent motion during the dipole pulse. That this structure was getting “worse” was not particularly obvious and does not particularly correlate with polarization loss. But it may be important. We need to quantify the structure and pay attention to it. *Fig 3 & 4*

The (magnet-power supply) system for the AC dipole was not healthy. Will be better next time.

4) **Up-the-Ramp measurement clearly showed no polarization loss as the beam passed through the $G\gamma=48$ -v resonance region, where a 10 % loss is expected.** *mystery!*

The measurement looks good. Can our machine and model differ enough to explain this? *Fig 5*

Maybe we can make some measurements of the AGS beta function around the machine using the response of the beam position monitors to dipole orbit distortions.
